

Presence of riparian vegetation increases biotic condition of fish assemblages in two Brazilian reservoirs

A vegetação ripária aumenta a condição biótica da assembleia de peixes em dois reservatórios brasileiros

Abstract: The riparian vegetation in lakes and reservoirs is source of course wood structures such as trunks and branches and is used as sheltering, spawning and foraging habitats for fishes. The reduction of these submerged structures can thus, affect the composition and structure of fish assemblages in reservoirs. **Aim:** To evaluate the influence of riparian vegetation on the biotic condition of fish assemblage by adapting the Reservoir Fish Assemblage Index (RFAI) to two reservoirs in the Upper Paranapanema river basin, São Paulo State, Brazil. **Methods:** The RFAI was adapted from metrics related to the functional characteristics and composition of fish assemblages through a protocol of metric selection and validation, and to its response to the presence of riparian vegetation. **Results:** The final RFAI was composed by nine metrics, been lower in sites without riparian vegetation as consequence of the predominance of larger individuals and the percent of piscivorous and detritivorous fishes. **Conclusions:** These results suggest that increasing shore habitat complexity in reservoirs by maintaining riparian vegetation increases fish biotic integrity.

Keywords: small hydropower plants; RFAI; habitat complexity; biotic integrity; high Paranapanema River Basin.

Resumo: A vegetação ripária em lagos e reservatórios provê estruturas como troncos e galhos que são utilizados como locais de refúgio, desova e alimentação para espécies de peixes. A diminuição destas estruturas submersas pode afetar a composição e estrutura das comunidades de peixes em reservatórios. **Objetivo:** Avaliar a influência da vegetação ripária sobre a condição biótica das assembleias de peixes por meio da adaptação do Índice de Assembleia de Peixes em Reservatórios (IAPR) a duas represas na bacia do Alto Paranapanema, Estado de São Paulo, Brasil. **Métodos:** O IAPR foi adaptado a partir de métricas referentes às características funcionais e à composição das assembleias de peixes por meio de um protocolo de seleção e validação e de sua resposta à presença de vegetação ripária. **Resultados:** O IAPR final foi composto por nove métricas, sendo menor em locais sem vegetação, em função da predominância de indivíduos de grande porte, percentual de piscívoros e detritívoros. **Conclusões:** Os resultados sugerem que o aumento na complexidade de habitats litorais em reservatórios por meio da manutenção da vegetação ripária aumenta a integridade biótica em peixes.

Palavras-chave: pequenas centrais hidrelétricas; IAPR; complexidade de habitat; integridade biótica; Bacia do Alto Paranapanema.

1. Introduction

Restoration actions in environments under anthropogenic pressures require identifying keystone structures that will help maintaining regional species diversity and biological condition (Tews et al., 2004). In lakes, keystone elements are generally related to underwater structures as artificial reefs, submerged trees or natural coarse woody debris that promote habitat heterogeneity for fishes and invertebrates (Freitas & Petreire Junior, 2001; Sass et al., 2006; Santos et al., 2011; Gois et al., 2012).

The loss of wood debris are among the highest sources of fish habitat degradation in reservoirs across United States (Miranda et al., 2010). Removal of these coarse woody habitats (CWH) has complex effects on ecosystem functioning by altering percent of sheltering and spawning habitats and predator-prey interactions (Roth et al., 2007). Helmus & Sass (2008) for example, showed that experimental removal of CWH resulted in a rapid declining of the yellow perch (*Perca flavescens* (Mitchill, 1814)) abundance, probably due to losing of sheltering habitats and spawning structures. In another experiment, the piscivorous fish largemouth bass (*Micropterus salmoides* (Lacepede, 1802)) reduced its home range and lowering its consumption rates after CWH removal, while the opposite pattern was observed after CWH placement (Ahrenstorff et al., 2009).

A natural source of wood debris and trunks is the riparian vegetation, which also influence physical and chemical processes through local temperature control, enhancing bank stability and being source of terrestrial invertebrates for fishes (Washington, 2009). Kaufmann et al. (2014) showed that the structural complexity of riparian cover in lakes are positively correlated with richness of intolerant taxa over a broad range of anthropogenic disturbance, thus being an element promoting biological integrity.

In this study we investigate whether the presence of riparian vegetation enhances condition of fish assemblages in two small reservoirs at southeast Brazil. Assemblage condition was measured by the Reservoir Fish Assemblage Index (RFAI), a multimetric index developed to detect and monitor ongoing impacts on fish biota (Jennings et al., 1995; McDonough & Hickman, 1999; Petesse et al., 2007a; Terra & Araújo, 2010).

Multimetric indices (MIs) has been used for about three decades to evaluate the quality of aquatic environments (Karr, 1981; Fausch et al.,

1984; Hughes et al., 2010) and incorporates attributes from the biota that are sensitive to habitat degradation (Angermeier & Karr, 1994). MIs was largely adapted to streams and rivers (Lyons et al., 1995; Ganasan & Hughes, 1998; Araújo et al., 2003; Bozzetti & Schulz, 2004; Pinto et al., 2006; Ferreira et al., 2007; Whittier et al., 2007; Zhu & Chang, 2008; Casatti et al., 2009; Hermoso et al., 2010), lakes and wetlands (Gassner et al., 2003; Irz et al., 2008; Wilson et al., 2013), and reservoirs (Jennings et al., 1995; McDonough & Hickman, 1999; Petesse et al., 2007a; Terra & Araújo, 2010).

By their own nature, reservoirs lack reference areas free of anthropogenic disturbances. Thus adaptation of MIs to such environments has to define the kind of disturbance and to which spatial scale the index will be applied. Here, disturbance refers to the lack of riparian vegetation and the scale refers to segments of the shore area within the reservoir with or without riparian vegetation. Thus, the MI herein adapted (hereafter RFAI) aims to differentiate shoreline segments with riparian vegetation from those where riparian vegetation were removed. We presented a protocol based on the literature for metric selection, calculation and validation of the RFAI.

2. Material and Methods

2.1. Study area

We sampled two reservoirs (Paineiras and Jorda Flor) in the Turvo river at the headwater of the Upper Paranapanema river basin in the São Paulo State (southeastern Brazil) (Figure 1). The region includes small towns, each with less than 30 thousand inhabitants. The agriculture is the most important economic activity, being the

Figure 1. Location of the reservoirs in Brazil and position of the sampling sites in dry (circles) and wet seasons (triangles). Light gray symbols indicates sites with riparian vegetation.

water demand estimated in 1.64 m³/s for urban use, 4.49 m³/s for industry and 21.7 m³/s for irrigation (São Paulo, 2009). The Turvo river has a drainage area of 1,617 km² and 70 km extension, crossing only one urban area, the town of Pilar do Sul, which 684.22 km² and 26.2 thousands of inhabitants, 30% living in the rural zone (IBGE, 2009). The precipitation is about 1,300 mm/year with a dry season between April and September (average of 63 mm/month) and a wet season between October and March (average of 159 mm/month). The average temperatures vary from 23.4 °C between January and March to 16.5 °C between June and July (CEPAGRI, 2011).

The Paineiras reservoir has a longitudinal axis of 10 km, a volume of 35.35 × 10⁶ m³ and a 32 m high dam. It was built in 1912 to supply the Batista power plant, one of the oldest SHPs of the São Paulo State that nowadays generates 2,704 kW (CSPE, 2004). The Jorda Flor reservoir has 2 km of extension, 250 m wide, 1.2 × 10⁶ m³ and a dam of 26.5 m high. It was built in 1949 and generates 1,392 kW (CSPE, 2004). The littoral zones in the reservoirs are composed by secondary forest, pasture and eucalypt plantation, and the reservoirs do not receive significant amounts of urban effluents, as they are above the town of Pilar do Sul. As the majority of the oldest SHPs, there are no fish passages connecting the reservoirs to the lower portions of the basin. In addition, there is a waterfall of approximately 20 m high isolating the Paineiras reservoir from the upstream portion of Turvo river basin. The water retention time and the variability in the operational water level were not available.

2.2. Fish sampling

In each season (dry - September and wet - December 2009), seven sites were sampled in Paineiras reservoir and three in Jorda Flor. Sampling took seven days of fieldwork in each season. In each reservoir, the sampling locations were spatially separated by 1000 m on average, placed at increasing distances from the dam. The fishes were caught using 10 gillnets (mesh sizes from 3 to 12 cm between opposite knots) measuring 20 m length and between 1.50 and 2.40 m high. In order to capture small fishes, we complemented the samples with two funnel traps. The gillnets were positioned perpendicularly to the shore line of the reservoirs and the funnel traps were placed in the margins beside the gillnets. Gillnets and funnel traps were let in the water from late afternoon to the next morning (approximately 12 hours). In September

we lost one gillnet battery in Jorda Flor, so that the total data set consisted of 19 samples (Figure 1).

All fishes were fixed in 10% formalin and, in the laboratory identified at the species level, weighed (grams) and measured (standard length – cm). The species abundance was expressed as capture per unit of effort in number of individuals (CPUE_N) and weight (CPUE_w). Thus, CPUE represented the number of fishes or total weight captured by 400 m² of gillnets plus the two funnel traps. Voucher specimens were photographed and deposited at the fish collection of the Departamento de Zoologia e Botânica da Universidade Estadual Paulista, São José do Rio Preto, São Paulo State.

The species were classified by their trophic guild as piscivorous, insectivorous, omnivorous, and herbivorous or detritivorous, defined after the analysis of 850 stomachs. The riparian vegetation at each sampling location was coded as 0 - Absent/Fragmented (no vegetation or only sparse trees) or 1 - Present (dense riparian vegetation). After sampling we registered the limnological variables: temperature (°C), pH, conductivity (µS cm⁻¹), turbidity (NTU) and dissolved oxygen (mg l⁻¹), using an electronic device (Horiba, model U-10). The average depth was measured with a demarcated rope (precision of 10 cm).

2.3. Metric selection

The 15 candidate metrics represented ecological attributes of the fish assemblages relating to (i) species richness, (ii) abundance, (iii) trophic structure, and (iv) reproduction. Some metrics were adapted from the literature, while others were proposed in this study (Table 1). The literature of multimetric indexes, reservoir and fish ecology helped predicting the expected behavior of the candidate metrics with disturbance. The protocol of metric selection was based on the criteria of variability, responsiveness and redundancy (Whittier et al., 2007). The variability criterion consisted in excluding metrics with low discriminatory power, considered those with at least 50% of equal values. Other authors have considered the limit of 75% (Whittier et al., 2007; Rehn et al., 2008), but we decided for a lower limit due to the small number of sampling sites. The concept of responsiveness in adaptation of MI refers to the response of the biological metrics to environmental variables. As there as several metrics and several environmental variables it was evaluated by means of a canonical redundancy analysis (RDA), a multivariate version of multiple regression (Legendre & Legendre, 2012). We used the metrics

Table 1. Description of the candidate metrics and their expected behavior in response to disturbance.

i - Species richness	Expected Response to disturbance
1. <i>Total number of native species (S)</i> : As in other adaptations of multimetric indexes, the number of native species is expected to decrease with anthropic degradation following pollution, loss of habitat diversity or introduction of non-native species.	Decrease
ii - Abundance	
2. <i>W statistic from ABC curve (W)*</i> : This method was proposed by Warwick (1986) and Clarke (1990) as a tool to infer about the effect of anthropic stress on the biota. The assumption is that less disturbed assemblages have larger and long live species, which in general are less abundant, but have higher dominance in weight. In this case, the dominance in weight is higher than in number of individuals and W has positive values. In disturbed environments, it is expected a predominance of small and opportunistic species that have high abundance but low biomass, resulting in negative values of W (Magurran, 2004). The metric was calculated by $W = \frac{\sum_{i=1}^S B_i - A_i}{50(S-1)}$, where B_i = the species weight in score i , A_i = the species numeric abundance in score i and S = species richness. The response of ABC curve to damming was analyzed by Penczak & Agostinho (1997) in Segredo reservoir, and by Gonçalves & Braga (2008) in the SHP Mogi-Guaçu. The pattern followed the expected behavior in all examples.	Decrease
3. <i>Percent of dominance (PDOM)</i> : The percent of dominance of the most abundant species is an indicative of habitat simplification (McDonough & Hickman, 1999) and was used in Brazilian reservoirs by Petesse et al. (2007a) and by Terra & Araújo (2010).	Increase
4. <i>Total number of individuals (N)</i> : This metric assumes that the total abundance decreases with disturbance. As different fish groups can vary in their response to environmental disturbance, the metric is complemented by the next three metrics (number 5 to 7) referent to different fish Orders and Families.	Decrease
5. <i>Percent abundance of Characiformes (CHAR)*</i> : This metric was used to evaluate fishes that use the water column, have visual orientation and are capable to colonize a wide variety of habitats. It was used in substitution to Characiformes richness (Araújo et al., 2003; Petesse et al., 2007a; Terra & Araújo, 2010), with justify in situation such as the present study were there is a small number of species (Magalhães et al., 2008).	Decrease
6. <i>Percent abundance of Siluriformes (SIL)*</i> : This metric intends to evaluate the benthic habitats as a substitution for the number of sucker species proposed by Karr (1981). The number of Siluriformes was first used in African rivers by Hugueny et al. (1996), and in Brazilian rivers and reservoirs by Araújo et al. (2003), Bozzetti & Schulz (2004), Petesse et al. (2007a) and Terra & Araújo (2010). It is assumed that the abundance of Siluriformes is reduced by the degradation of benthic habitat, which in reservoir can occur as result of siltation or oxygen depletion.	Decrease
7. <i>Percent abundance of Cichlidae (CICH)*</i> : This metric was considered in substitution for Cichlidae species richness used by Petesse et al. (2007a) as an indicator of degradation of the littoral zones used to nest construction.	Decrease
8. <i>Percent abundance of introduced species (INTR)*</i> : Used in substitution for the metric number of introduced species (Araújo et al., 2003; Petesse et al., 2007a). In reservoirs where these species are established, there are in general negative effects on native assemblage structure.	Increase
9. <i>Percent abundance of individuals larger than 30 cm (L30)</i> : This metric was proposed by Petesse et al. (2007a) to evaluate the decrease of k-strategists species in favor of r-strategists. The dominance of r-strategists was verified by Gonçalves & Braga (2008) in the SHP Mogi-Guaçu.	Decrease
iii - Trophic structure	
10. <i>Weight percent of piscivorous (PIS)</i> : Piscivorous species are in the top of aquatic foodwebs and their abundance indicates an assemblage well diversified and structured (Karr, 1981). For all metric related to trophic structure it was use the weight percent because it is a better indicator of energy assimilation and transfer in foodwebs.	Decrease
11. <i>Weight percent of insectivorous (INS)</i> : Insectivorous species, especially those feeding on allochthonous items are dependent on riparian vegetation well structured (Casatti, 2002; Esteves & Aranha, 1999; Menezes et al., 2007; Sabino & Castro, 1990).	Decrease
12. <i>Weight percent of omnivorous (OMNI)</i> : A metric related to omnivory was proposed by Karr (1981) as evidence of disruption of the foodweb base. These species are in general opportunistic and predominate when the foodweb is simplified.	Increase
13. <i>Weight percent of detritivorous (DET)*</i> : It is proposed to evaluate the increase in detritus sedimentation favoring the species that use this alimentary resource.	Increase

* Metrics proposed in the present study.

Table 1. Continued...

iii - Trophic structure	Expected Response to disturbance
14. <i>Weight percent of herbivorous (HER)*</i> : The number of herbivorous species was used by Araújo et al. (2003) and Petesse et al. (2007a). This metric intent to evaluate the contribution of species with high-specialized diet, which should be sensible to habitat disruption (Ganasan & Hughes, 1998; Petesse et al., 2007a). In Neotropical reservoirs this group is naturally rare (Agostinho et al., 2007).	Decrease
iv - Reproduction	
15. <i>Weight percent of species with parental care (PC)*</i> : This metric was used to evaluate the effect of disruption of littoral zones resulted from siltation or hydrological stress (Petesse et al., 2007b). The species with parental care (<i>Geophagus brasiliensis</i> , <i>Hoplias malabaricus</i> , <i>Hoplosternum littorale</i> , <i>Oreochromis niloticus</i> and the genera <i>Hypostomus</i>) were based on Suzuki et al. (2005).	Decrease

* Metrics proposed in the present study.

as response and the environmental variables as the explanatory matrix. Metrics that did not correlate (Pearson correlation coefficient, $p > 0.05$) with any of the RDA axes were excluded. The statistical significance of the RDA axes was verified by a permutation procedure (5,000 randomizations). The criterion of redundancy aimed to identify pairs of metrics that expressed the same kind of information. If two metrics were considered redundant (Pearson correlation coefficient ≥ 0.70) the one with the lowest responsiveness were excluded.

2.4. Metric scoring and RFAI calculation

After selecting the metrics each value were ranked with the scores 1, 3 or 5, using as reference the best observed condition (Jennings et al., 1995). For metrics in which high values indicate high environmental quality, the 95th percentile were identified and the observed distribution trisected in the 63th and 32th percentiles. The score 5 was given to values above the 63th percentile, the score 1 to those below the 32th percentile, and the score 3 to values in between these percentiles. For metrics that decrease with anthropic stress, it was considered the values above the 5th percentile and inverted the scores 1 and 5.

The RFAI for each site were obtained summing the individual scored metrics. To verify if the RFAI differed between reservoirs and seasons a two way ANOVA was applied and to identify the most influence metrics it was calculated the Pearson correlation coefficient between the RFAI and each metric. Statistically significant relationships with the environmental variables were used to validate the index. It was done by calculating the Pearson correlation between the RFAI and the limnological variables and depth, and performing a t test to verify the influence of riparian vegetation. A potential source of confusion was the fact that only one site

in the Jorda Flor reservoir had riparian vegetation. Therefore, the t test was repeated only for the Paineiras reservoir in order to see if the results change.

3. Results

3.1. Assemblage composition

Samples yielded 1,952 individuals within five orders, nine families, and 15 species. Each reservoir had 12 species and similar CPUE_N. Nonetheless, the CPUE_w was approximately 1.6 times greater in Paineiras reservoir. The most abundant species were *Geophagus brasiliensis* (Quoy & Gaimard, 1824) and *Astyanax altiparanae* Garutti & Britski, 2000, whereas *Hoplias malabaricus* (Bloch, 1794) and *G. brasiliensis* accounted for the highest total weight. *Schizodon nasutus* Kner, 1858 and *Oligosarcus paranensis* Menezes & Géry, 1983 occurred only in Jorda Flor while *Hyphessobrycon anisitsi* (Eigenmann, 1907), *Piabina argentea* Reinhardt, 1867 and *Gymnotus carapo* Linnaeus, 1758 only in the Paineiras reservoir. The fish assemblages was composed by five trophic groups. Omnivorous were the most common (8 species), whereas insectivorous, detritivorous and piscivorous were represented by two species each, and herbivorous by only one (*Schizodon nasutus*). The two piscivorous species (*H. malabaricus* and *Rhamdia quelen* (Quoy & Gaimard in Freycinet, 1824) represented 50.3% of the CPUE_w in Paineiras reservoir and only 16.7% in Jorda Flor (Table 2).

3.2. Metric selection

Only two introduced species (*Oreochromis niloticus* (Linnaeus, 1758) - 17 individuals and *Cyprinus carpio* Linnaeus, 1758 - 9 individuals) were caught, they represented less than 1% of total CPUE_N, 2.7% of total CPUE_w and were absent

in 10 (52.6% of total) out of the 19 samples. Insectivorous species were absent in 12 sites (63.2%) and herbivorous in 14 (73.7%). Therefore, the metrics related to abundance of introduced species (INTR), percent of insectivorous (INS) and percent

of herbivorous (HER) were excluded from the RFAI due to low variability.

Only the first two RDA axes were statistically significant, explaining 18.2% ($p = 0.003$) and 12.6% ($p = 0.022$) of total variability. Species

Table 2. Species captured in the Paineiras and Jorda Flor reservoirs. CPUE_N - capture per unit of effort in number of individuals; CPUE_w - capture per unit of effort in weight (grams).

richness (S) and percent of dominance (PDOM) did not pass in the responsiveness test, as they were not correlated with any of these axes. The first RDA axis expressed the gradients of conductivity and turbidity and the presence/absence of riparian vegetation. It was correlated with the percent of larger individuals (L30, $r = 0.63$, $p = 0.004$), species with parental care (PC, $r = 0.72$, $p < 0.001$), percent of piscivorous (PIS, $r = 0.47$, $p = 0.042$), positive values of W statistic ($r = 0.76$, $p < 0.001$), and small percent of Characiformes (CHAR, $r = -0.61$, $p = 0.006$). The second axis expressed a gradient of depth, being correlated positively with the percent of Cichlidae (CICH, $r = 0.65$, $p = 0.003$), number of individuals (N, $r = 0.50$, $p = 0.028$) and percent

of omnivorous (OMNI, $r = 0.67$, $p = 0.001$), and negatively with the percent of Siluriformes (SIL, $r = -0.72$, $p < 0.001$) and detritivorous species (DET, $r = -0.54$, $p = 0.017$). The correlation between CHAR and CICH indicated that these metrics were redundant ($r = -0.70$). We excluded CHAR because it had the lowest responsiveness, i.e. the weakest correlation with the RDA axes (Figure 2).

3.3. Validation of RFAI

After selecting the metrics, nine composed the final RFAI (Table 3). Two are expected to increase with disturbance and seven to decrease (Table 1). The RFAI varied from 13 to 41, being significantly correlated with W statistic ($r = 0.56$, $p = 0.012$), percent of larger individuals ($r = 0.71$, $p = 0.001$), piscivorous ($r = 0.70$, $p = 0.001$) and detritivorous ($r = -0.56$, $p = 0.012$), and marginally correlated with the predominance of individuals with parental care ($r = 0.42$, $p = 0.076$) (Table 3). The Jorda Flor reservoir had lower integrity (mean $RFAI_{\text{Jorda Flor}} = 19$, mean $RFAI_{\text{Batista}} = 29.14$, $F_{1;15} = 11.12$, $p = 0.005$, Figure 3a), the sampling season did not influence the RFAI (mean $RFAI_{\text{dry}} = 25.4$, mean $RFAI_{\text{wet}} = 27.4$, $F_{1;15} = 1.06$, $p = 0.320$, Figure 3b), and there was no interaction between reservoir and season ($F_{1;15} = 0.72$, $p = 0.410$). Among the limnological variables, only conductivity was marginally correlated with the RFAI ($r = -0.42$, $p = 0.071$, Table 4).

Sites without riparian vegetation had on average lower integrity than those with riparian vegetation (mean $RFAI_{\text{no riparian vegetation}} = 22.3$, mean $RFAI_{\text{with riparian vegetation}} = 30.2$, $t = 2.75$, $df = 17$, $p = 0.014$), and this pattern did not change if only the Paineiras reservoir is considered (mean $RFAI_{\text{no riparian vegetation}} = 24.6$, mean $RFAI_{\text{with riparian vegetation}} = 31.7$, $t = 2.38$, $df = 12$, $p = 0.034$) (Figure 3c).

Figure 2. Results of the Redundancy Analysis (RDA) showing the two significant axes ($p \leq 0.05$). Black circles: Paineiras reservoir. Open circles: Jorda Flor reservoir. See Table 1 for metrics that correspond to abbreviations.

Table 3. Observed intervals and limits used to score the metrics. See Table 1 for metrics that correspond to abbreviations.

Metrics	Scores			Pearson correlation with RFAI			
	1	3	5	Worst value	Best value	r	p
W ($\times 10^{-4}$)	< 2.42	2.42-5.79	> 5.79	-11	25	0.56	0.012

Table 4. Relationship among the RFAI and the environmental variables.

	RFAI	Mean (standard deviation)	Maximum and minimum
Depth (m)	$r = 0.25, p = 0.312$	3.43 (1.75)	1.00-8.00
Temperature (°C)	$r = 0.38, p = 0.112$	22.51 (2.61)	17.90-26.00
Turbidity (NTU)	$r = -0.29, p = 0.227$	40.79 (51.69)	3.00-154.00
pH	$r = 0.10, p = 0.672$	6.81 (0.64)	5.22-7.80
Dissolved Oxygen (mg ^l ⁻¹)	$r = 0.17, p = 0.482$	6.73 (1.88)	3.50-9.20
Conductivity (µScm ⁻¹)	$r = -0.42, p = 0.071$	26.47 (0.15)	25.00-29.00

**Figure 3.** Distribution (median, 25th and 75th percentiles, and extreme values) of the RFAI index comparing the reservoirs (a), seasons (b) and presence of riparian vegetation (c).

4. Discussion

Riparian vegetation has several influences on the functioning of lentic ecosystems such as local temperature control, shade, bank stability, providing structures that enhances underwater habitat complexity such as wood debris and trunks (Washington, 2009). These structures are used as spawning, foraging and shelter habitats for fishes (Sass et al., 2006).

Some authors have found that littoral zones with riparian vegetation and the presence of aquatic macrophytes are positively correlated with fish diversity (Amaral & Petre Junior, 2001; Gomes et al., 2012), and that the presence of submerged trees increases the fish abundances (Gois et al., 2012). Experimental studies also proved that enhancing the underwater habitat complexity by means of artificial reefs or natural CWH structures increases fish diversity, and affects assemblage dynamics and trophic interactions (Freitas &

Petre Junior, 2001; Ahrenstorff et al., 2009; Santos et al., 2011).

Adaptations of multimetric indexes to Brazilian reservoirs are recent and aimed to detect the influence of river-reservoir gradient in fish community condition (Petesse et al., 2007a; Terra & Araújo, 2010). Our adaptation focusing on evaluate the effects of sections of shoreline with and without riparian vegetation and found that biotic condition of fish assemblages was higher in the first. Biotic condition was not influenced by the limnological variables, depth or season, suggesting that RFAI were more sensitive to the structural shoreline heterogeneity than to the limnological variables. RFAI was also lower in Jorda Flor reservoir, where only one sampling location had riparian vegetation.

Four metrics (W statistic, L30, PIS and DET) were statistical correlated with the final RFAI.

L30 measures directly the percent of larger individuals in the samples, while the W statistic is a measure of relative dominance of biomass over numerical abundance. Local samples were riparian vegetation is absent had a predominance of small individuals that in general are abundant but have lower biomass. W statistic was proposed by Warwick (1986) to indicate locations under pollution stress, where community was composed mainly by small bodied-size organisms within abundant populations.

The other two metrics (PIS and DET) expressed the influence of riparian vegetation on the trophic structure of fish communities. In Paineiras reservoir, piscivorous biomass represented 50.3% of total capture whereas in Jorda Flor only 16.7%. When piscivorous biomass is high, a strong influence of predation on trophic structure is expected (Pelicice et al., 2005). The habitat patches provided by material from riparian vegetation is suggested as the structures that intermediate trophic interactions helping support such high piscivorous biomass. *H. malabaricus* for example, is an ambusher predator that adopt a sit-and-wait

strategy to feed (Mazzeo et al., 2010) and submerged trunks and wood debris may provide the necessary foraging habitats. In this case, the removal of riparian vegetation may indirectly reduce predation efficiency and piscivorous abundance by means of reducing the number of submerged CWH structures (Ahrenstorff et al., 2009).

Detritivorous fishes have a specialized diet that in the present study were represented by two loricariids (*Hypostomus ancistroides* and *H. margaritifera*). We found no studies relating the influence of riparian vegetation removal and detritivory abundance, but the lack of shore line vegetation may increase the entering of sediments and fine detritus, thus increasing the source of food for these species.

We found no influence of metrics related to total species richness and number of introduced species which is probably attributed to the low number of species in the Paineiras and Jorda Flor reservoirs, a characteristic that are common to other small hydropower plants in headwater areas. In addition, Luiz et al. (2005) verified that the frequency of occurrence of introduced species was lower in the Paranapanema river basin than in other river basins of the state of Paraná.

We provided an evaluation of the influence of riparian vegetation on fish assemblage condition in two small headwater reservoirs and provided a protocol for metric selection and validation based on literature. The method can be extended to other reservoirs of the Paranapanema river basin. With more reservoirs included, the natural variability in age, size, and longitudinal position along the river basin should be taken in account, because these variables influence species richness and assemblage composition (Agostinho et al., 2007; Gerritsen et al., 2003; Luiz et al., 2005). After removing the effects of natural variability, the sampling of different environments within the reservoirs will allow identifying point sources of disturbances that reduce the habitat complexity and consequently the fish integrity.

Acknowledgements

This study was supported by the Fundação de Amparo à Pesquisa do Estado de São Paulo - FAPESP (Thematic Project: *Ecologia de Represas*, #2007/50981-7 and the associated scholarships #2007/50982-3 and #2009/10804-4). Dr. Francisco Langeani helped us with fish identification and IBAMA provided us with the license for fish collection.
